A blind source separation technique using second order statistics

Adel Belouchrani, IEEE member, Karim Abed-Merai, IEEE member,
Jean-François Cardoso, IEEE member and Eric Moulines, IEEE member

Abstract— Separation of sources consists in recovering a set of signals of which only instantaneous linear mixtures are observed. In many situations, no a priori information on the mixing matrix is available: the linear mixture should be ‘blindly’ processed. This typically occurs in narrow-band array processing applications when the array manifold is unknown or distorted.

This paper introduces a new source separation technique exploiting the time coherence of the source signals. In contrast to other previously reported techniques, the proposed approach relies only on stationary second-order statistics, being based on a joint diagonalization of a set of covariance matrices. Asymptotic performance analysis of this method is carried out; some numerical simulations are provided to illustrate the effectiveness of the proposed method.

I. INTRODUCTION

In many situations of practical interest, one has to process multidimensional observations of the form:

\[ \mathbf{x}(t) = \mathbf{y}(t) + \mathbf{n}(t) = \mathbf{A}s(t) + \mathbf{n}(t), \]

\( i.e., \) \( \mathbf{x}(t) \) is a noisy instantaneous linear mixture of source signals. This model is commonplace in the field of narrow band array processing. In this context, vector \( \mathbf{s}(t) = [s_1(t), \ldots, s_n(t)]^T \) contains the signals emitted by \( n \) narrow band sources; vector \( \mathbf{y}(t) = [y_1(t), \ldots, y_n(t)]^T \) contains the array output sampled at time \( t \); matrix \( \mathbf{A} \) is the transfer function between sources and sensors. In the following, it is referred to as the ‘array matrix’ or the ‘mixing matrix’.

Most array processing techniques rely on the modeling of \( \mathbf{A} \); each column of \( \mathbf{A} \) is assumed to depend on a small number of parameters. This information may be provided either by physical modeling (for example, when the array geometry is known and when the sources are in the far-field of the array) or by direct array calibration. In many circumstances however, this information is not available or not reliable.

Blind source separation consists in identifying \( \mathbf{A} \) and/or retrieving the source signals without resorting to any a priori information about mixing matrix \( \mathbf{A} \): it exploits only the information carried by the received signals themselves, hence the term blind. Performance of such blind techniques is, by nature, essentially unaffected by potential errors in the propagation model or in array calibration (this is obviously not the case of parametric array processing technique: see, for example [1], [2]). Of course, the lack of information on the structure of \( \mathbf{A} \) must be compensated by some additional assumptions on source signals.

For non-Gaussian independent sources, the first approach traces back to the pioneering adaptive algorithm of Jutten-Hrault [3] (see also [4], [5], [6], [7]). Batch algorithms, based mainly on higher-order cumulants, have been later developed; see, for instance [8], [9], [10], [11]. These algorithms exploit only the marginal distribution of the observations. Thus, they are suitable even when source signals are temporally independent. Otherwise, other approaches can be developed, based on temporal correlations. Since these are second order statistics, they are expected to be more robust in adverse signal to noise ratios.

For cyclostationary emitters, like those encountered in digital or analog communication systems, a sound approach consists in exploiting spectral redundancy at the cyclic frequency of the sources of interest, as proposed in [12]. However, these methods crucially rely on the assumption that the different sources have different cyclostationary features [13]. In addition, when the cyclic frequencies are not known in advance, they must be estimated.

A different context is considered herein: stationary sources with different spectral contents. It has been already shown that blind identification is feasible based on spatial covariance matrices [14], [15], [16], [17]. These matrices (see below) show a simple structure which allows straightforward blind identification procedures based on eigendecomposition. In this paper, we introduce a blind identification technique, based on a joint diagonalization of several covariance matrices. Robustness is significantly increased, at low additional cost, by processing such a matrix set rather than a unique matrix as in [14].

The paper is organized as follows. In section II, the problem of blind source separation is stated together with the relevant hypothesis. Section III presents a second order blind identification technique based on ‘joint diagonalization’ of a set of spatial covariance matrices; an efficient Jacobi-like algorithm for solving this problem is described in appendix A. In section IV, a closed-form expression of the asymptotic performance of the proposed method is derived. Numerical simulation illustrating the validity of this method are presented in section V.
II. PROBLEM FORMULATION

A. Assumptions

We start by specifying the signal. It is assumed that the source signal vector \( \mathbf{s}(t) \) is either (H1) a deterministic ergodic sequence or (H2) a stationary multivariate process with

\[
(H1): \quad \lim_{T \to \infty} T^{-1} \sum_{t=1}^{T} \mathbf{s}(t + \tau) \mathbf{s}(t)^* = \begin{cases} \mathbf{K} & \text{if } \tau = 0 \\ \mathbf{0} & \text{otherwise} \end{cases}
\]

\[
(H2): \quad E(\mathbf{s}(t + \tau) \mathbf{s}(t)^*) = \mathbf{R}_s(\tau) = \text{diag}[\rho_1(\tau), \ldots, \rho_n(\tau)]
\]

where superscript * denotes the conjugate transpose of a vector and diag[.] is the diagonal matrix formed with the elements of its vector valued argument. For convenience, the same notation \( E \) is used for the deterministic averaging operation under hypothesis (H1) and for ensemble averaging under (H2). This convention holds throughout. Assumptions (H1) or (H2) mean that the component processes \( \mathbf{s}_i(t) \), \( 1 \leq i \leq n \) are mutually uncorrelated and \( \rho_i(\tau) = E(\mathbf{s}_i(t + \tau) \mathbf{s}_i(t)^*) \) denotes the auto-covariance of \( \mathbf{s}_i(t) \).

The additive noise \( \mathbf{n}(t) \) is modeled as a stationary, temporally white, zero-mean complex random process independent of the source signals. For simplicity, we also require \( \mathbf{n}(t) \) to be spatially white, i.e.

\[
E(\mathbf{n}(t + \tau) \mathbf{n}^*(t)) = \sigma^2 \delta(\tau) \mathbf{I}
\]

where \( \delta(\tau) \) is the Kronecker delta and \( \mathbf{I} \) denotes the identity matrix. The assumption of spatially white noise is not crucial: the method presented below may be extended to the case of an unknown noise covariance matrix (see section III-A).

The \( m \times n \) complex matrix \( \mathbf{A} \) is assumed to have full column rank but is otherwise unknown. In contrast to traditional parametric methods, no specific array geometry or sensor characteristics are assumed, i.e. the array manifold is unknown.

Under the above assumptions, the covariance matrices of the array output take the following structure:

\[
\begin{align*}
\mathbf{R}(0) &= E(\mathbf{x}(t)\mathbf{x}^*(t)) = \mathbf{AR}_s(0)\mathbf{A}^H + \sigma^2 \mathbf{I} \\
\mathbf{R}(\tau) &= E(\mathbf{x}(t + \tau)\mathbf{x}^*(t)) = \mathbf{AR}_s(\tau)\mathbf{A}^H \quad \tau \neq 0
\end{align*}
\]

where superscript \(^H\) denotes the complex conjugate transpose of a matrix. The aim of blind source separation is to identify the mixture matrix and/or recover the source signals from the array output \( \mathbf{x}(t) \) without any prior knowledge of the array manifold. The potential benefit of such a blind approach is that source separation is essentially unaffected by errors in the propagation model or in array calibration.

B. Blind identifiability

Before proceeding, it is important to specify the notion of blind identification. In the blind context, a full identification of the mixture matrix \( \mathbf{A} \) is impossible because the exchange of a fixed scalar factor between a given source signal and the corresponding column of \( \mathbf{A} \) does not affect the observations as is shown by the following relation:

\[
\mathbf{x}(t) = \mathbf{A}\mathbf{s}(t) + \mathbf{n}(t) = \sum_{p=1}^{n} \frac{\mathbf{a}_p}{\alpha_p} \alpha_p \mathbf{s}_p(t) + \mathbf{n}(t)
\]

where \( \alpha_p \) is an arbitrary complex factor and \( \mathbf{a}_p \) denotes the \( p \)-th column of \( \mathbf{A} \).

Advantage can be taken of this indeterminacy by assuming, without any loss of generality, that the source signals have unit variance, so that the dynamic range of the sources is accounted for by the magnitude of the corresponding columns of \( \mathbf{A} \). This normalization convention turns out to be convenient in the sequel; it does not affect the performance results presented below. Since the sources are assumed to be uncorrelated, we have

\[
\mathbf{R}_s(0) = \mathbf{I}
\]

so that \( \mathbf{R}_s(0) \overset{\text{def}}{=} E(\mathbf{y}(t)\mathbf{y}^*(t)) = \mathbf{AA}^H \).

This normalization still leaves undetermined the ordering and the phases of the columns of \( \mathbf{A} \). The following definition is then in order:

**Definition 1:** Two matrices \( \mathbf{M} \) and \( \mathbf{N} \) are said to be essentially equal if there exists a matrix \( \mathbf{P} \) such that \( \mathbf{M} = \mathbf{NP} \) where \( \mathbf{P} \) has exactly one non-zero entry in each row and column, these entries having unit modulus. This is denoted \( \mathbf{M} \overset{\#}{=} \mathbf{N} \).

In this paper, blind identification of \( \mathbf{A} \) is understood as the determination of a matrix essentially equal to \( \mathbf{A} \). Of course, these indeterminacies do not impede source separation: if the mixture matrix \( \mathbf{A} \) is estimated up to permutation and phase shifts, it is still possible to determine the source signals up to the corresponding fixed permutation and phase shifts (blind identifiability is discussed at length in [18]).

III. A SECOND ORDER IDENTIFICATION APPROACH

A. Whitening

The first step of our procedure consists in whitening the signal part \( \mathbf{y}(t) \) of the observation. This is achieved by applying to \( \mathbf{y}(t) \) a whitening matrix \( \mathbf{W} \), i.e. a \( n \times m \) matrix verifying:

\[
E(\mathbf{W}\mathbf{y}(t)\mathbf{y}^*(t)^H) = \mathbf{W}\mathbf{R}_y(0)\mathbf{W}^H = \mathbf{W}\mathbf{A}^H\mathbf{W}^H = \mathbf{I}.
\]

Equation (10) shows that if \( \mathbf{W} \) is a whitening matrix, then \( \mathbf{WA} \) is a \( n \times n \) unitary matrix. It follows that for any whitening matrix \( \mathbf{W} \), there exists a \( n \times n \) unitary matrix \( \mathbf{U} \) such that \( \mathbf{WA} = \mathbf{U} \). As a consequence, matrix \( \mathbf{A} \) can be factored as:

\[
\mathbf{A} = \mathbf{W}\#\mathbf{U}
\]

where superscript \(#\) denotes the Moore-Penrose pseudo-inverse. We note that this whitening procedure reduces the determination of the \( m \times n \) mixture matrix \( \mathbf{A} \) to that of a unitary \( n \times n \) matrix \( \mathbf{U} \). The whitened process \( \mathbf{z}(t) = \mathbf{W}\mathbf{x}(t) \) still obeys a linear model:

\[
\mathbf{z}(t) \overset{\text{def}}{=} \mathbf{W}\mathbf{x}(t) = \mathbf{W} (\mathbf{A}\mathbf{s}(t) + \mathbf{n}(t)) = \mathbf{Us}(t) + \mathbf{Wn}(t)
\]
the signal part of the whitened process now is a ‘unitary mixture’ of the source signals. Note that all information contained in the covariance is ‘exhausted’ after the whitening procedure, in the sense that changing $\mathbf{U}$ in (12) to any other unitary matrix leaves the covariance of $\mathbf{z}(t)$ unchanged. Note also that besides whitening the signal part of the observations, multiplication by a whitening matrix $\mathbf{W}$ reduces the array output to a $n$-dimensional vector.

Since we have from equations (6) and (9) $\mathbf{A} \mathbf{A}^H = \mathbf{R}(0) - \sigma^2 \mathbf{I}$, equation (10) shows that a whitening matrix $\mathbf{W}$ can be determined from the array output covariance $\mathbf{R}(0)$ provided the noise covariance matrix is known or can be estimated. A whitening matrix may also be determined from a linear combination of a set of covariance matrices taken at non zero time lags, as suggested in [14]. In any case, as shown by (11), finding a whitening matrix still leaves undetermined a unitary factor in $\mathbf{A}$. This ‘missing factor’ $\mathbf{U}$ can be determined from higher-order statistics as investigated in [10], [8], [9]. Exploiting the time dependence structure (hypothesis H1 or H2), it may be also retrieved from covariance matrices at non zero lags, as explained below.

B. Determining the unitary factor

Consider the spatially whitened covariance matrix $\mathbf{R}(\tau)$ defined as

$$\forall \tau \neq 0 \quad \mathbf{R}(\tau) = \mathbf{W} \mathbf{R}(\tau) \mathbf{W}^H.$$  \hfill (13)

These $n \times n$ complex matrices are nothing but the covariance matrices of the process $\mathbf{z}(t)$. By (7) and (11), we obtain the key relation:

$$\forall \tau \neq 0 \quad \mathbf{R}(\tau) = \mathbf{U} \mathbf{R}_s(\tau) \mathbf{U}^H.$$  \hfill (14)

Since $\mathbf{U}$ is unitary and $\mathbf{R}_s(\tau)$ is diagonal, the latter means that

**Property:** Any whitened covariance matrix is diagonalized by the unitary transform $\mathbf{U}$.

As a consequence, the unitary factor $\mathbf{U}$ may be obtained as a unitary diagonalizing matrix of a whitened covariance matrix $\mathbf{R}(\tau)$ for some lag $\tau$. More formally,

**Theorem 1** (First uniqueness condition) Let $\tau$ be a non-zero time lag and $\mathbf{V}$ be a unitary matrix such that:

$$\mathbf{V}^H \mathbf{R}(\tau) \mathbf{V} = \text{diag}[d_1, \ldots, d_n]$$  \hfill (15)

$$\forall 1 \leq i \neq j \leq n \quad \rho_i(\tau) \neq \rho_j(\tau).$$  \hfill (16)

Then,

- $\mathbf{V}$ is essentially equal to $\mathbf{U}$: $\mathbf{V} \equiv \mathbf{U}$,
- it exists a permutation $\sigma$ on $\{1, \ldots, n\}$, such that:

$$\left[\rho_1(\tau), \ldots, \rho_n(\tau)\right] = \left[d_{\sigma(1)}, \ldots, d_{\sigma(n)}\right]$$

This property is a direct consequence of the spectral theorem for normal matrices (see for example [19], Theorem 2.5.4). We recall that an $n \times n$ matrix $\mathbf{M}$ is said to be normal if $\mathbf{M} \mathbf{M}^H = \mathbf{M}^H \mathbf{M}$. The spectral theorem states that a normal matrix $\mathbf{M}$ is unitarily diagonalizable, i.e. there exists a unitary matrix $\mathbf{U}$ and a diagonal matrix $\mathbf{D}$, such that $\mathbf{M} = \mathbf{U} \mathbf{D} \mathbf{U}^H$. In our setting, the existence of the unitary matrix $\mathbf{V}$ (15) for any time lag $\tau$ is guaranteed by equation (14). In contrast, the existence of a time lag $\tau \neq 0$ such that (16) holds is not trivial and cannot be checked *a priori*. Note that the indeterminacies (phase shifts and permutations) in the diagonalization of a normal matrix correspond precisely to those encountered in the blind source separation problem. Thus, the diagonalization of $\mathbf{R}(\tau)$ for a delay $\tau$ yields the relevant parameters if $\mathbf{R}(\tau)$ has distinct eigenvalues. This identification scheme may be found in slightly different forms in [14] and in [15].

True indeterminacy arises in the case of degenerate eigenvalues. It does not seem possible to determine *a priori* a time lag $\tau$ such that the eigenvalues of $\mathbf{R}(\tau)$ are distinct. Of course, if the source signals have different spectral shapes, eigenvalue degeneracy is unlikely, but the problem is not purely academic because it is to be expected that when an eigenvalue of $\mathbf{R}(\tau)$ comes close to degeneracy, the robustness of determining $\mathbf{U}$ from an eigendecomposition is seriously affected.

The situation is more favorable if we consider simultaneous diagonalization of a set $\{\mathbf{R}(\tau_i)\}_{i = 1, \ldots, K}$ of $K$ whitened covariance matrices.

**Theorem 2** (Second uniqueness condition) Let $\tau_1, \tau_2, \ldots, \tau_K$ be $K$ non-zero time lags and let $\mathbf{V}$ be a unitary matrix such that:

$$\forall 1 \leq i < j \leq K \quad \mathbf{V}^H \mathbf{R}(\tau_i) \mathbf{V} = \text{diag}[d_{i1}, \ldots, d_{in}]$$  \hfill (17)

$$\forall 1 \leq i \neq j \leq n \quad \exists k, 1 \leq k \leq K \quad d_{ik} \neq d_{jk}. \hfill (18)$$

Then,

- $\mathbf{V}$ is essentially equal to $\mathbf{U}$: $\mathbf{V} \equiv \mathbf{U}$,
- it exists a permutation $\sigma$ on $\{1, \ldots, n\}$, such that:

$$\left[\rho_1(\tau_k), \ldots, \rho_n(\tau_k)\right] = \left[d_{\sigma(1)}, \ldots, d_{\sigma(n)}\right]$$

This is a consequence of the essential uniqueness of joint diagonalization: see theorem 3 below. Again, the existence of a unitary matrix $\mathbf{V}$ that simultaneously diagonalizes the set of covariance matrices $\{\mathbf{R}(\tau_1), \ldots, \mathbf{R}(\tau_K)\}$ is guaranteed for any choice of time lags thanks to (14). Even though condition (18) is much weaker than condition (16), it is not necessarily true; in particular, in the trivial case where the sources show identical normalized spectra, the mixing matrix $\mathbf{A}$ cannot be identified by resorting to theorem 2. Conversely, when the source signals have different normalized spectra, it is always possible to find a set of time lags $\tau_1, \ldots, \tau_K$ such that condition (18) is met. This corresponds to the second order identifiability condition found in [18].

The main point of our contribution is to consider the joint diagonalization of several covariance matrices. This approach is intended to reduce the probability that an unfortunate choice of time lag $\tau$ results in un-identifiability of $\mathbf{U}$ from $\mathbf{R}(\tau)$; more importantly this approach generally increases the statistical efficiency of the procedure by inferring the value of $\mathbf{U}$ from a larger set of statistics.
C. Joint diagonalization

In numerical analysis, the ‘off’ of an $n \times n$ matrix $M$ with entries $M_{ij}$ is defined as

$$
\text{off}(M) \triangleq \sum_{1 \leq i < j \leq n} |M_{ij}|^2.
$$

(19)

and the unitary diagonalization of a matrix $M$ is equivalent to zeroing $\text{off}(V^H M V)$ by some unitary matrix $V$. As recalled above, the spectral theorem states that only normal matrices can be unitarily diagonalized. In addition, if a matrix $M$ is in the form $M = UDU^H$ where $U$ is unitary and $D$ is diagonal with distinct diagonal elements, then it may be unitarily diagonalized by unitary matrices which are essentially equal to $U$, that is: if $\text{off}(V^H M V) = 0$ then $V \equiv U$.

Consider a set $\mathcal{M} = \{M_1, \ldots, M_K\}$ of $K$ matrices of size $n \times n$. The ‘joint diagonality’ (JD) criterion is defined, for any $n \times n$ matrix $V$, as the following non-negative function of $V$:

$$
C(\mathcal{M}, V) \triangleq \sum_{k=1}^{K} \text{off}(V^H M_k V)
$$

(20)

A unitary matrix is said to be a joint diagonalizer of the set $\mathcal{M}$ if it minimizes the JD criterion (20) over the set of all unitary matrices.

Let us first consider the case where each matrix in the set $\mathcal{M}$ is in the form $M_k = U_k D_k U_k^H$ with $U_k$ a diagonal matrix. Then, clearly $C(\mathcal{M}, U) = 0$ and this is the global minimum of the JD criterion (20) since $C(\mathcal{M}, V) \geq 0$ for any matrix $V$. Thus, if each matrix in the set $\mathcal{M}$ can be unitarily diagonalized by $U$, then, according to our definition, matrix $U$ is a joint diagonalizer of $\mathcal{M}$. This is of little interest: we are more interested in the uniqueness of a joint diagonalizer. We have the following

Theorem 3 (Essential uniqueness of joint diagonalization)

Let $\mathcal{M} = \{M_1, \ldots, M_K\}$ be a set of $K$ matrices where, for $1 \leq k \leq K$, matrix $M_k$ is in the form $M_k = U_k D_k U_k^H$ with $U_k$ a unitary matrix and $D_k = \text{diag}(d_1(k), \ldots, d_n(k))$. Any joint diagonalizer of $\mathcal{M}$ is essentially equal to $U$ if, and only if

$$
\forall 1 \leq i \neq j \leq n \exists k, 1 \leq k \leq K \text{ } d_i(k) \neq d_j(k).
$$

(21)

The essential uniqueness condition (21) is of course much weaker than the requirement that each matrix in $\mathcal{M}$ is uniquely unitarily diagonalizable. In particular, it is easy to construct examples where each matrix in $\mathcal{M}$ has a degenerate eigenvalue spectrum but such that the joint diagonalizer of $\mathcal{M}$ is nonetheless essentially unique. The proof of theorem 3 is given in appendix -B.

An important feature of our definition of joint diagonalization is that it is not required that the matrix set under consideration can be exactly simultaneously diagonalized by a single unitary matrix. As a matter of fact, it is not even required that the matrices in the set are individually unitarily diagonalizable. This is because we do not require that the ‘off’ of all the matrices are cancelled by a unitary transform; a joint diagonalizer is just a minimizer of the JD criterion. If the matrices in $\mathcal{M}$ are not in the form considered in theorem 3, the JD criterion cannot be zeroed and the matrices can only be approximately jointly diagonalized. Hence, an (approximate) joint diagonalizer defines a kind of an ‘average eigen-structure.’ This is particularly convenient for statistical inference where the structural information is to be extracted from sample statistics: even though the true covariance matrices considered above can be exactly simultaneously diagonalized, their sample counterparts cannot, because of the estimation errors. Hence, rather than exactly diagonalizing a single covariance matrix, the approximate joint diagonalization allows the information contained in a set of covariance matrices to be integrated in a single unitary matrix.

Another important feature of the (possibly approximate) joint diagonalization is the existence of a numerically efficient algorithm for its computation. This algorithm is a generalization of the Jacobi technique for the exact diagonalization of a single hermitian matrix [20]. This technique consists in computing the unitary diagonalizer as a product of Givens rotations. It turns out that the Givens rotation parameters can be simply computed even when the matrices to be joint-diagonalized do not show any symmetry property. This is particularly convenient for processing sample covariance matrices which have no reason of being exactly normal. The extension of the Jacobi technique to approximate joint diagonalization is described in appendix -A.

D. Implementation of the SOBI algorithm

Based on the previous sections, we can introduce a Second Order Blind Identification (SOBI) algorithm. SOBI is defined by the following implementation.

1. Estimate the sample covariance $R(0)$ from $T$ data samples. Denote by $\lambda_1, \ldots, \lambda_n$ the $n$ largest eigenvalues and $h_1, \ldots, h_n$ the corresponding eigenvectors of $R(0)$.

2. Under the white noise assumption, an estimate $\sigma^2$ of the noise variance is the average of the $m - n$ smallest eigenvalues of $R(0)$. The whitened signals are $z(t) = [z_1(t), \ldots, z_T(t)]^T$, computed by $z_i(t) = (\lambda_i - \sigma^2)^{-\frac{1}{2}} h_i^t x(t)$ for $1 \leq i \leq n$. This is equivalent to forming a whitening matrix by $W = [(\lambda_1 - \sigma^2)^{-\frac{1}{2}} h_1, \ldots, (\lambda_n - \sigma^2)^{-\frac{1}{2}} h_n]^H$.

3. Form sample estimates $\widehat{R} \{\tau\}$ by computing the sample covariance matrices of $z(t)$ for a fixed set of time lags $\tau \in \{\tau_j | j = 1, \ldots, K\}$.

4. A unitary matrix $U$ is then obtained as joint diagonalizer of the set $\{\widehat{R} \{\tau_j\} | j = 1, \ldots, K\}$.

5. The source signals are estimated as $s(t) = U^H W x(t)$ and/or the mixing matrix $A$ is estimated as $A = W^H U$.

IV. Asymptotic Performance Analysis

In this section, an asymptotic performance analysis of the proposed method is carried out. To ease the deriva-
tions, we make the following additional assumptions.

**H1.** Each source signal $s_i(t)$ is a circular stationary Gaussian process: $E(s_i(t + \tau)s_i(t)) = 0$ for $1 \leq i \leq n$ and any time lag $\tau$.

**H2.** The source signals $s_i(t)$ are mutually independent and are independent of the noise $n(t)$.

**H3.** The source signals are short range dependent, in the sense that $\sum_{l \in Z} |\rho_l(\tau)| < \infty$.

Hypothesis H3 is an extremely mild condition which is verified, for example, by all AR or ARMA processes. To get rid of phase and permutation indeterminacies, we shall assume that they are fixed in such a way that the matrix estimator $\hat{A}$ is close to the true mixture matrix $A$ rather than to some other matrix essentially equal to $A$. Also, the covariance matrices are computed at time lags $\tau_1, \ldots, \tau_K$ such that the uniqueness condition of theorem 2 is verified.

### A. Performance index

Rather than estimating the variance of the coefficients of the mixing matrix, it is more relevant to source separation to compute an index which quantifies the performance in terms of interference rejection, as follows. Assume that, at each time instant $t$, an estimate of the vector of source signals is computed by applying to the received signal $x(t)$ the pseudo-inverse of the estimated mixture matrix, i.e.

$$s(t) = \hat{A}^#x(t) = \hat{A}^#As(t) + \hat{A}^#n(t)$$

(22)

where $\hat{A}^#$ is given by $\hat{A}^# = U^H W$. We stress that in general, this procedure is not optimal for recovering the source signals based on an estimate $\hat{A}$. For large enough sample size $T$, matrix $\hat{A}$ should be close to the true mixing matrix $A$ so that $\hat{A}^#A$ is close to the identity matrix. The performance index used in the sequel is the interference to signal ratio (ISR), defined as:

$$I_{pq} = E|\langle \hat{A}^#A \rangle_{pq}|^2$$

(23)

This actually defines an ISR because, by our normalization convention (9), we have $I_{pp} \simeq 1$ for large enough $T$. Thus $I_{pq}$ measures the ratio of the power of the interference of the $q$-th source to the power of the $p$-th source signal estimated as in (22). As a measure of the overall quality of the separation, we also define a global rejection level:

$$I_{perf} \overset{\text{def}}{=} \sum_{q \neq p} I_{pq}$$

(24)

### B. Outline of performance analysis

The asymptotic variance of the estimates of $A$ is expected to decrease as $1/T$ thanks to the short range dependence of the observed process (assumption H3). Thus, the leading term of $I_{pq}$ is of order $T^{-1}$. The purpose of this section is to give its close form expression. Detailed computations are not reported herein due to lack of space. We rather outline the computation below and give further details in appendix.

Asymptotic performance is obtained along the following lines. We note that matrix estimate $\hat{A}$ is a ‘function’ of the sample covariance matrices $(\hat{R}(0), \hat{R}(\tau_1), \ldots, \hat{R}(\tau_K))$ of the observed signal $x(t)$. The computation can then proceed in two steps; first, we express the asymptotic moments of the sample covariance matrices (see lemma 1); second, we compute the leading term (in the sample covariance matrices) in the Taylor expansion of $|\langle \hat{A}^#A \rangle_{pq}|^2$ (see lemma 2). The final result is obtained by combining these two expressions.

**Lemma 1:** Under conditions H1’, H2’ and H3, and for any matrices $M$ and $N$ in $\Phi_{m \times n}$:

$$\lim_{T \to \infty} \frac{1}{T} \text{Tr} \{ \delta R(\tau_k) M \delta R(\tau_k) N \} = \sum_{\tau \in Z} \text{Tr} \{ R(\tau_k + \tau) N \} \text{Tr} \{ R(\tau_k - \tau) M \}$$

(25)

$$\lim_{T \to \infty} \frac{1}{T} \text{Tr} \{ \delta R(\tau_k) M \} \text{Tr} \{ \delta R(\tau_j) N \} = \sum_{\tau \in Z} \text{Tr} \{ M R(\tau_k + \tau) N R(\tau_j - \tau) \}$$

(26)

$$\lim_{T \to \infty} T \| \delta R(\tau_k) \|^2 = 0$$

(27)

where $\delta R(\tau_k) = R(\tau_k) - R(\tau_k)$ and $\text{Tr} \{ M \}$ denotes the trace of matrix $M$.

**Proof:** see [21].

**Lemma 2:** The Taylor expansion of $|\langle \hat{A}^#A \rangle_{pq}|^2$ is given for $p \neq q$ by:

$$|\langle \hat{A}^#A \rangle_{pq}|^2 = \left| \int_{0}^{\theta} (C(pq) - C(qp)) \right|^2$$

(28)

$$+ \sum_{\tau \in Z} \alpha_{pq}(\tau) C(pq)(\tau) + C(qp)(\tau)$$

(29)

$$+ \sum_{k \neq p, q} \alpha_{pq}(k) C(pq)(\tau_k) + O(\| \delta R(\tau_k) \|^2)$$

(30)

where $\alpha_{pq}(\tau) = \text{Tr} (H \hat{R}(\tau) \bar{H})$ and $\| \delta R(\tau_k) \|^2$ for $k \neq 0$.

**Proof:** See appendix - C.

According to lemma 2, the expectation of $|\langle \hat{A}^#A \rangle_{pq}|^2$ can be computed from the expectations of $|C(pq)(\tau)|^2$, $C(pq)(\tau_k)$ and $C(qp)(\tau_k)$. Lemma 1 reduces this computation to simple algebra, yielding:

$$E|C(pq)(\tau)|^2 = \frac{1}{4T} \left[ |C(pq)(\tau)|^2 + \sigma^2 (J_{pp} + J_{qq}) + \sigma^2 (J_{pp} + J_{qq}) \right]$$

(31)

$$E(C(pq)(\tau) C(qp)(\tau)) = -\frac{1}{4T} \left[ C(pq)(\tau) + \sigma^2 (J_{pp} \rho_{pq} + J_{qq} \rho_{pq}(k)) + J_{pp} \rho_{pq}(k) \right]$$

(32)

$$E(C(pq)(\tau) C(qp)(\tau)) = \frac{1}{4T} \left[ C(pq)(\tau) + \sigma^2 (J_{pp} \rho_{pq} + J_{qq} \rho_{pq}(k)) + J_{pp} \rho_{pq}(k) \right]$$

(33)
where we have set
\[
D_{pq}(k) = \int \frac{f_p(\lambda) f_q(\lambda)}{\sqrt{2\pi}} \exp\left(2i\pi\lambda \tau_k\right) d\lambda
\]
\[
J_{pq} = (\mathbf{A}^H \mathbf{A})^{-1}
\]
and where \( f_p \) denotes the spectral density of the \( p \)-th source signal. Using the above, the ISR is asymptotically given by
\[
I_{pq} = I^0_{pq} + \sigma^2 I^1_{pq} + \sigma^4 I^2_{pq} \tag{25}
\]
where the coefficients of the expansion are

\[
I^0_{pq} = \frac{1}{4T} \left[ \alpha_{pq}(0)^2 D_{pq}(0) - 2\alpha_{pq}(0) \sum_{1 \leq |i| \leq K} \alpha_{pq}(k) D_{pq}(k) \right.
\]
\[
+ \sum_{1 \leq |i| \leq K} \alpha_{pq}(k) \alpha_{pq}(i) D_{pq}(k + i) \left. \right]
\]

\[
I^1_{pq} = \frac{1}{4T} \left[ (\alpha_{pq}(0)^2 - 2\alpha_{pq}(0) \sum_{1 \leq |i| \leq K} \alpha_{pq}(k) \rho_p(k) \right.
\]
\[
+ \sum_{1 \leq |i| \leq K} \alpha_{pq}(k) \alpha_{pq}(i) \rho_p(k + i)) J_{pp} \left. \right]
\]
\[
+ (\alpha_{pq}(0)^2 - 2\alpha_{pq}(0) \sum_{1 \leq |i| \leq K} \alpha_{pq}(k) \rho_p(k) \right.
\]
\[
+ \sum_{1 \leq |i| \leq K} \alpha_{pq}(k) \alpha_{pq}(i) \rho_p(k + i)) J_{qq} \left. \right]
\]
\[
I^2_{pq} = \frac{1}{4T} \left[ \frac{\alpha_{pq}(0)^2 |J_{pq}|^2}{m - n} + J_{pp} J_{qq} (\alpha_{pq}(0)^2) + \frac{2}{|\rho_p - \rho_q|^2} \right]
\]

\[\]

C. Discussion

For high signal to noise ratio, the expansion (25) of the ISR is dominated by the first term \( I^0_{pq} \). This term shows two important features.

- \( I^0_{pq} \) is proportional to the spectral overlap of sources \( p \) and \( q \). If the sources \( p \) and \( q \) have no spectral overlap (i.e. their frequency supports are disjoint), \( f_p(\lambda) f_q(\lambda) = 0 \) for all \( \lambda \), the corresponding ISR given by \( I_{pq} \) vanishes at first order. More generally, the ISR in the high SNR limit is proportional to the spectral overlap (this effect is illustrated in the next section).

- \( I^0_{pq} \) is independent of the mixing matrix. In the array processing context, it means that performance in terms of interference rejection are unaffected (surprisingly enough) by the array geometry, and in particular, by the number of sensors. The performance depends solely upon the spectral overlap of the source signals.

This (maybe surprising) phenomenon has been investigated in a more general context in [22].

In the above algorithm, the covariance matrices involved in the joint diagonalization criterion (20) are uniformly weighted. Note that the JD criterion could be generalized by weighting each ‘off’ term by an appropriate factor. Optimal weighting could, at least theoretically, be obtained by extending the previous derivations. This point is left to further study.

V. PERFORMANCE EVALUATION

This section investigates the performance of the SOBI algorithm by computer simulations. The validity of the asymptotic performance analysis is also assessed.

A. Numerical simulations

In the simulated environment, a 5-element uniform linear array with half wavelength sensor spacing receives two signals in the presence of stationary complex white noise. The two sources are unit-variance, complex circular Gaussian with different but overlapping spectra. The sources arrive from different directions \( \phi_1 = 12 \) and \( \phi_2 = 13 \) degrees (the particular structure of the array manifold is of course not exploited by the SOBI algorithm). The snapshot size is \( T = 1000 \) samples; the mean overall rejection level is estimated by averaging 300 independent trials.

Example 1: The source signals are generated by filtering a complex circular white Gaussian processes by an AR model of order 1 with coefficient \( a_1 = \rho_1 \exp(i\theta_1) \) and \( a_2 = \rho_2 \exp(i\theta_2) \). The time lags implicitly involved are \( \tau_1, \ldots, \tau_k \), where \( \tau_i \) is \( i \) times the time unit.

In figure 1, the rejection level \( I_{perf} \) is plotted in dB as a function of the number of the jointly diagonalized covariance matrices for SNR=10 dB. The modulus of the AR coefficients of the two sources is \( \rho_1 = \rho_2 = 0.85 \); the angles are respectively equal to \( \theta_1 = 0.5 \) and \( \theta_2 = 0.55 \); we are dealing here with sources presenting a large spectral overlap.

This figure shows a performance gain reaching 9 dB by diagonalizing six matrices rather than only one. We have found experimentally that the most significant gain in performance are obtained in difficult environments: poor SNR, small spectral difference, ill-conditioned mixture matrix, etc.

In figure 2, the noise level is kept constant at 5 dB and \( \theta_1 = 0.5 \). We let \( \theta_2 \) vary as \( \theta_2 = \theta_1 + \delta \theta \). On the plot, the curves are labeled with the number of covariance matrices used in the identification. The plot shows the rejection level \( I_{perf} \) in dB plotted as against the ‘spectral shift’ \( \delta \theta \). The plot evidences a significant increase in rejection performance by including 2 or 8 covariance matrices in the joint diagonalization criterion.

Example 2: In this example, we compare the performance of the SOBI algorithm with the Self-Coherence restoral (SCORE) algorithm presented in the paper by Agee, Schell and Gardner [12]. In contrast with SOBI, the SCORE method assumes that the source signals are cyclostationary with different cyclic frequencies.

In this experiment the first source is a first-order autoregressive Gaussian process \( \phi = 0.85, \theta = 0 \) modulated by a complex exponential with normalized frequency \( \alpha_1 = 0.3 \) (the signal is thus cyclostationary with cyclic frequency 2\( \alpha_1 \)). The second source is also a first order autoregressive
Gaussian process \((\rho = 0.85, \theta = 0)\) modulated by a complex exponential with normalized frequency \(\alpha_2 = \alpha_1 + \delta \alpha\). Herein the SOBI algorithm is used by jointly diagonalizing 4 covariance matrices.

The performance measure used to judge the quality of the processor output signal is the mean rejection level as defined in section IV-A. In figure 3 the noise level is kept constant at -10 dB and the mean rejection level is plotted in dB as a function of the spectral shift \(\delta \alpha\) which is also half the difference between the two cyclic frequencies \(2\alpha_1\) and \(2\alpha_2\).

It is seen in figure 3 that the SCORE method is less sensitive than SOBI to small values of \(\delta \alpha\). In contrast for large spectral shift \(\delta \alpha\) the SOBI algorithm allows a performance gain reaching 10 dB.

In figure 4, spectral shift \(\delta \alpha\) is kept constant at 0.4. The noise level is varied between -25 dB and 0 dB. The plot shows the mean rejection level in dB as a function of the noise power \(\sigma^2\). This figure demonstrates that in the case of large spectral shift the SOBI method shows a performance gain of 10 dB compared to SCORE algorithm.

Of course it would be wrong to claim that the SOBI method yields consistently better results than the SCORE method. We only want to claim that, in the situations where the sources are sufficiently separated in the stationary frequency domain, the SOBI algorithm yields acceptable results.

As a final note, we want to stress that the spectral separation of the sources is essential for the SOBI method; it is not required by the SCORE algorithm (or the further refinements of it [23, 13]), which is able to separate signals with a complete spectral overlap provided they show different cyclostationary features.

In figure 5, the rejection level \(I_{\text{perf}}\) is plotted in dB as a function of the noise power \(\sigma^2\) (also expressed in dB). The sources are first-order autoregressive with parameters \(\rho_1 = \rho_2 = 0.85\) and angle \(\theta_1 \approx 0.5\) and \(\theta_2 = \theta_1 + \delta \theta\). On the plots, the curves are labeled with the spectral shift \(\delta \theta\). We note that the approximation is better at high SNR and for large spectral shift. This means that the asymptotic conditions are reached faster in this range of parameters.

In figure 6, the rejection level \(I_{\text{perf}}\) is plotted in dB as against sample size. On the plots, the curves are labeled as the function of the noise power \(\sigma^2\) in dB. This figure shows that the asymptotic closed form expressions of the rejection levels are pertinent from a snapshot length of about 100 samples. This means that asymptotic conditions are reached even for small data block size.

VI. Conclusion

This paper presents a new blind source separation technique for temporally correlated sources. It is based on the joint diagonalization of an arbitrary set of covariance matrices. This method shows a number of attractive features: i) it relies only on second order statistics of the received signals, ii) allows in contrast to higher order cumulant techniques, the separation of Gaussian sources, iii) the use of several covariance matrices (in contrast to the previous proposal by [14]) makes the algorithm more robust: for practical purposes, it makes very unlikely indeterminacies. Numerical experiments show the benefit of exploiting several covariance matrices in difficult contexts (low SNR, sources with little spectral difference). The main steps of the computation of the asymptotic performance analysis are also given.

Acknowledgments

The authors would like to express this sincere thanks to Prof. P. Duhamel for his useful comments on an early version of this paper.

Appendix

A. A joint approximate diagonalization algorithm

The Jacobi technique [20] for diagonalizing a unique hermitian matrix is extended for the joint approximate diagonalization of a set of normal matrices. The proposed method consists in minimizing the JD criterion (20) by successive Givens rotations, which leads to solving the same problem for \(K \times 2 \times 2\) matrices:

\[
H_k = \begin{bmatrix}
    a_k & b_k \\
    c_k & d_k
\end{bmatrix}
\]  

(26)
for \( k = 1, \ldots, K \). A unitary matrix \( \mathbf{V} \) is sought such that
\[
\mathbf{H}_k^* = \mathbf{V}^H \mathbf{H}_k \mathbf{V} \quad (k = 1, \ldots, K)
\]
minimizes the criterion (20). The unitary transformation \( \mathbf{V} \) is parameterized by a complex Givens rotation:
\[
\mathbf{V} = \begin{bmatrix}
\cos \theta & e^{j \phi} \sin \theta \\
-e^{-j \phi} \sin \theta & \cos \theta
\end{bmatrix}.
\] (27)

Denoting by \( a'_k, b'_k, c'_k \) and \( d'_k \) the coefficients of \( \mathbf{H}_k^* \), optimization of (20) amounts to finding \( \theta \) and \( \phi \) such that
\[
\sum_k |a'_k|^2 + |d'_k|^2
\]
is maximized. Noticing that \( 2( |a'_k|^2 + |d'_k|^2 ) = |a_k|^2 - d_k^4 + |b'_k|^2 + |d'_k|^2 \) and that the trace \( a'_k + d'_k \) is invariant in a unitary transformation, optimization of criterion (20) is equivalent at each Givens step to the maximization of \( Q \):
\[
Q \overset{\text{def}}{=} \sum_k |a'_k - d_k|^2.
\] (28)

It is easily checked that
\[
a'_k - d_k = (a_k - d_k) \cos \theta - (b_k + c_k) \sin \theta \cos \phi
\]
\[
- j(c_k - b_k) \sin \theta \sin \phi
\] (29)
for \( k = 1, \ldots, K \). Then by defining the vectors
\[
\mathbf{u}^T \overset{\text{def}}{=} [a'_1 - d'_1, \ldots, a'_K - d'_K]
\] (30)
\[
\mathbf{v}^T \overset{\text{def}}{=} [\cos 2 \theta, - \sin 2 \theta \cos \phi, - \sin 2 \theta \sin \phi]
\] (31)
\[
\mathbf{g}_k \overset{\text{def}}{=} [a_k - d_k, b_k + c_k, j(c_k - b_k)]
\] (32)
the \( K \) equations (29) may be written in the form \( \mathbf{u} = \mathbf{G} \mathbf{v} \)
where \( \mathbf{G} \overset{\text{def}}{=} [\mathbf{g}_1, \ldots, \mathbf{g}_K] \) so that \( Q \) also reads
\[
Q = \mathbf{u}^H \mathbf{u} = \mathbf{v}^H \mathbf{G}^H \mathbf{G} \mathbf{v} = \mathbf{v}^T \Re(\mathbf{G}^H \mathbf{G}) \mathbf{v}
\] (33)
where we have used the fact that, \( \mathbf{G}^H \mathbf{G} \) being hermitian by construction, its imaginary part is anti-symmetric and hence contributes nothing to the above quadratic form. The last step is to recognize that the particular parameterization (31) of \( \mathbf{v} \) is equivalent to the condition \( \mathbf{v}^T \mathbf{v} = 1 \). Maximizing a quadratic form under the unit norm constraint of its argument is classically obtained by taking \( \mathbf{v} \) to be the eigenvector of \( \Re(\mathbf{G}^H \mathbf{G}) \) associated to the largest eigenvalue. Recall that this is a real \( 3 \times 3 \) symmetric matrix; the analytic expressions of the parameters of the Givens rotation are simply derived from the coordinates of the eigenvector. The reader may check that setting \( K = 1 \) and \( \mathbf{H}_1 \) hermitian, the above boils down to the standard Jacobi procedure. Also note that the main cost in this kind of technique is the update under Givens rotations of the various matrices involved in the diagonalization. This makes clear that the cost of the proposed procedure is similar to \( K \) times the diagonalization of a single matrix.

B. Proof of theorem 3

The sufficiency of condition (21) is established by proving that any linear combination (with at least 2 non-zero factors) of the vectors \( \mathbf{u}_i, i = 1, \ldots, n \) cannot be a common eigenvector of the matrices \( \mathbf{M}_k, \ k = 1, \ldots, K \):
Let \( \mathbf{v} = \sum_{i \leq i \leq n} \lambda_i \mathbf{u}_i \) be a common eigenvector of the matrices \( \mathbf{M}_k, \ k = 1, \ldots, K \), and assume for example \( \alpha_1 \neq 0 \). According to condition (21), for any index \( i, \ 1 \leq i \leq n \), there exists an index \( k \) such that \( d_1(k) \neq d_i(k) \). For this index \( k \), we have by hypotheses
\[
\mathbf{M}_k \mathbf{v} = \lambda_k \mathbf{v}
\]
\[
= \sum_{j=1}^{n} \lambda_k \alpha_j \mathbf{u}_j
\]
and
\[
\mathbf{M}_k \mathbf{v} = \sum_{j=1}^{n} \alpha_j M_k \mathbf{u}_j
\]
\[
= \sum_{j=1}^{n} \alpha_j d_j(k) \mathbf{u}_j
\]
By identification, one have \( \alpha_j (d_j(k) - \lambda_k) = 0 \) for \( 1 \leq j \leq n \). Since \( \alpha_1 \neq 0 \) and \( d_1(k) \neq d_i(k) \) for \( k = 1, \ldots, K \), this leads to \( \lambda_k = d_1(k) \) and \( \alpha_1 = 0 \). Q.E.D.

Next we establish the necessity of condition (21). Assume that there exists a pair \((i, j)\) such that \( d_1(k) = d_j(k) \) for \( k = 1, \ldots, K \). Then any linear combination of the vectors \( \mathbf{u}_i \) and \( \mathbf{u}_j \) is a common eigenvector of the matrices \( \mathbf{M}_k, \ k = 1, \ldots, K \). Q.E.D.

C. Proof for lemma 2

In this section, a sketch of proof for lemma 2 is presented. Giving a full proof is a tedious and lengthy exercise, which goes far beyond the scope of this paper (it can be obtained upon author request). A part of the proof is based on the result on the perturbation of the joint diagonalization obtained in [24]. For brevity, this result is admitted.

The square modulus \( |I_{p(1)}|^2 \) is expressed as:
\[
|I_{p(1)}|^2 = |(\mathbf{U}^H \mathbf{W})_{p(1)}|^2
\] (34)
We decompose the matrix \( \mathbf{W} \mathbf{A} \) under its polar form:
\[
\mathbf{V} \mathbf{H} = \mathbf{W} \mathbf{A}
\] (35)
\( \mathbf{V} \) is a unitary matrix and \( \mathbf{H} \) is a non negative semi-defined hermitian matrix; matrix \( \mathbf{H} \) verifies \( \mathbf{H}^2 = \mathbf{A}^H \mathbf{W}^H \mathbf{W} \mathbf{A} \) (see [19], theorem 7.3.2, pp. 412). According to the convention outlined in section III-A, matrix \( \mathbf{H} \) is expected to be close to the identity matrix; let \( \delta \mathbf{H} = \mathbf{H} - \mathbf{I} \) denote the estimation error of the hermitian part of \( \mathbf{W} \mathbf{A} \). Using standard perturbation calculus (see, for example, [25]), it can be shown that:
\[
\delta \mathbf{H} = \frac{1}{2} \mathbf{A}^H \mathbf{R}(0) \mathbf{A}^H + \frac{1}{2(m-n)} \operatorname{Tr} (\Re(\mathbf{R}(0)) (\mathbf{A}^H \mathbf{A})^{-1}) + o(\delta \mathbf{R}(0)).
\] (36)
From the polar decomposition (35), the whitened covariance matrices can be similarly approximated at the first order, for all \( k \neq 0 \), as:
\[
\mathbf{R}(\tau_k) = \mathbf{W} (\mathbf{A} R_0(k) \mathbf{A}^H + \mathbf{R}(\tau_k) - \mathbf{R}(\tau_k)) \mathbf{W}^H
\]
\[
= \mathbf{V} (\mathbf{H} R_0(k) \mathbf{H}^H + \mathbf{V}^H \mathbf{W} \Re(\tau_k) \mathbf{W}^H \mathbf{V}) \mathbf{V}^H
\] (37)
The diagonalization criterion aims at searching the unitary matrix which minimizes the "off" of a set of matrices, here the whitened covariance matrix \( \mathbf{R}(\tau_0) \). It is not difficult to guess (through actually difficult to prove in mathematical terms due to the indeterminacies inherent to these kinds of problems, see a discussion in [22], [24]) that, if the set of matrices entering in the JD are multiplied by a common unitary matrix, then the result of the JD will simply be multiplied by this common matrix. Formally, let \( N_1, \ldots, N_p \) be arbitrary matrices and \( U \) an arbitrary unitary matrix; then, \( JD[\{N_1 U^H, \ldots, N_p U^H\} = UJD[\{N_1, \ldots, N_p\}] \). Applying this result in our situation it comes from (37) that the unitary matrix \( U \), resulting from the JD of the set of whitened covariance matrices \( \mathbf{R}(1), \ldots, \mathbf{R}(K) \) can be decomposed as

\[
\mathbf{U} = \mathbf{VU}_0
\]

where the matrix \( \mathbf{U}_0 \) minimizes the JD criterion for the matrices:

\[
M_k \overset{\text{def}}{=} \mathbf{HR}(k)\mathbf{H} + \mathbf{V}^{\dagger} \mathbf{WR}(\tau_k) \mathbf{W} \mathbf{V}^\dagger, \quad 1 \leq k \leq K
\]

\[
= \mathbf{R}_k(\mathbf{H}) + \mathbf{R}_k(\mathbf{H}) \mathbf{H} + \delta \mathbf{HR}_k(\mathbf{H}) + \mathbf{W} \mathbf{WR}(\tau_k) \mathbf{W} \mathbf{V}^\dagger + o(\delta(\tau_k))
\]

\[
= \mathbf{R}_k(\mathbf{H}) + \mathbf{R}_k(\mathbf{H}) \mathbf{H} + \delta \mathbf{HR}_k(\mathbf{H}) + \mathbf{A} \mathbf{A}^H + o(\delta(\tau_k))
\]

\[
= \mathbf{R}_k(\mathbf{H}) + \xi_k + o(\delta(\tau_k))
\]

where \( \xi_k \overset{\text{def}}{=} \mathbf{R}_k(\mathbf{H}) \mathbf{H} + \delta \mathbf{HR}_k(\mathbf{H}) + \mathbf{A} \mathbf{A}^H + o(\delta(\tau_k)) \).

Hence, equation (34) can be written as:

\[
|I_{pq}|^2 = |(\mathbf{U}_0^H \mathbf{H})_{pq}|^2.
\]

As shown in [24], the unitary matrix \( \mathbf{U}_0 \) is given at first order by:

\[
\mathbf{U}_0 = \mathbf{I} + \delta \mathbf{U}_0
\]

\[
\delta \mathbf{U}_0 = \frac{1}{2} \sum_{1 \leq r \neq s \leq K} (\alpha_{rs}(\tau_0) \Pi_r \Pi_s + \alpha^*_{rs}(\tau_0) \Pi_s \Pi_r) (\mathbf{u}_0^H = -\delta \mathbf{U}_0) \quad (38)
\]

where \( \Pi_r \) is the orthogonal projector on the \( r \)-th vector column \( \mathbf{e}_r \) of the identity matrix \( \mathbf{I}_n \).

The performance index becomes:

\[
|I_{pq}|^2 = |(\mathbf{I} - \delta \mathbf{U}_0)(\mathbf{I} + \delta \mathbf{H})_{pq}|^2
\]

\[
\simeq |\delta \mathbf{H} - \delta \mathbf{U}_0|_{pq}^2 \quad \text{for} \quad p \neq q \quad (39)
\]

Including expressions (36) and (38) in (39) leads to the Taylor expansion of lemma 2.
