

MPRI 2.18.2: Solutions for Quiz 1

1 2-process Peterson's algorithm

Suppose that p_0 executes the first two lines of its algorithm in the reverse order:

1. $\text{turn} = 1;$
2. $\text{flag}[0] = \text{true};$

Then the following execution scenario is possible:

(Note that we do not care about the order in which the first two lines are executed by p_1 .)

Here p_0 sets turn to 1, then p_1 sets turn to 0, $\text{flag}[0]$ to true (the order in which these two operations are performed does not matter) reads false in $\text{flag}[0]$ and proceeds to the critical section. Then p_0 reads 0 in turn and also proceeds to the critical section—a contradiction.

2 N-process Peterson's algorithm

Algorithm 1 N-process Peterson's algorithm

- 1: **Shared variables:**
 - 2: $\text{level}[0, \dots, N - 1] = \{-1\}$
 - 3: $\text{waiting}[0, \dots, N - 2] = \{-1\}$

 - 4: **Trying section: code for process p_i :**
 - 5: **for** m from 0 to $N - 2$ **do**
 - 6: $\text{level}[i] = m;$
 - 7: $\text{waiting}[m] = i;$
 - 8: **while**($\text{waiting}[m] == i \ \&\& \ (\exists k \neq i : \text{level}[k] \geq m)$);
 - 9: **Critical section:**
 - 10: ...
 - 11: **Exit section:**
 - 12: $\text{level}[i] = -1;$
-

Mutual exclusion. To prove that Algorithm 1 ensures the property of mutual exclusion, suppose, by contradiction, that it has an execution in which two processes are in their critical sections at some time t .

We say that a process p_i reached level ℓ ($\ell = 0, \dots, N - 1$) if it is in the critical section or $\text{level}[i]$ stores ℓ or a higher value. Thus, by our assumption, two processes reached level $N - 1$ at the same time.

Intuitively, a process that reached level ℓ is in the critical section or in the waiting phase ℓ or higher. By the algorithm, a process p_i executing its ℓ -th waiting phase should wait for every process that reached level ℓ to complete their critical sections, unless there is another process that wrote to $\text{waiting}[\ell]$ after p_i .

Suppose, inductively, that for some $\ell = N - 1$ down to 1, a set S of $N - \ell + 1$ processes reached level ℓ or higher at some time t_ℓ . (In the base case, $\ell = N - 1$ and we have a set of 2 such processes.)

By the algorithm, before time t_ℓ , every process $p_i \in S$ sets $\text{level}[i]$ to $\ell - 1$ and writes i in $\text{waiting}[\ell - 1]$. Without loss of generality, assume that p_i is the last process in S to update $\text{waiting}[\ell - 1]$ before t_ℓ , and let t' be the time when this happens. Hence, at time t' , for every other process in $p_j \in S$, $\text{level}[j]$ stores $\ell - 1$ or a higher value. Indeed, if at time t' , for some process $p_j \in S$, $\text{level}[j]$ stores a value less than $\ell - 1$, then to reach level ℓ by time t_ℓ , p_j must write j to $\text{waiting}[\ell - 1]$ at some time between t' and t_ℓ , contradicting the assumption that p_i is the last process in S to write to $\text{waiting}[\ell - 1]$ before t_ℓ .

Since $|S| = N - \ell + 1$ and $\ell \leq N - 1$, there is at least one process in S besides p_i . Thus, to reach level ℓ , between t' and t_ℓ , p_i must have read a value other than i in $\text{waiting}[\ell - 1]$: otherwise, p_i would have to wait until all other processes in S complete their critical sections and set their level variables to -1 . Thus, at some time $t_{\ell-1}$ between t' and t_ℓ , a process $p_k \notin S$ has written k in $\text{waiting}[\ell - 1]$. Thus, at time $t_{\ell-1}$, at least $|S| + 1 = N - \ell + 2$ processes reached level $\ell - 1$.

By induction, we derive that at some time t_0 , at least $N + 1$ process must have reached level 0, contradicting the fact that we have exactly N processes.

Starvation-freedom. Now we prove that Algorithm 1 ensures the property of starvation-freedom, i.e., assuming that no process fails in the trying, critical, or exit sections, every process in the trying section eventually enters its critical section. By the algorithm, the only possibility for a process in the trying section not to enter its critical section is to *block* in line 8 at some level $\ell = 0, \dots, N - 2$. A process p_i blocks at level ℓ if, after setting $\text{level}[i]$ to ℓ and $\text{waiting}[\ell]$ to i , it keeps reading $\text{waiting}[\ell]$ and $\text{level}[0, \dots, N - 1]$ to always find $\text{waiting}[\ell] == 1$ and $\text{level}[j] \geq \ell$ for some $j \neq i$. Since, prior to this, every process p_i writes i in $\text{waiting}[\ell]$, at most one process can be blocked at any given level.

Suppose, by contradiction that there exists a non-empty set of blocked processes, and let p_i be the process that is blocked at the highest level ℓ . Let t be the time when p_i writes i to `waiting` $[\ell]$ for the last time. Thus, any process p_j that reaches level ℓ must have written j to `waiting` $[\ell]$ before t : otherwise, p_i would eventually read a value other than i and “unblock”. Moreover, any such process that p_j must eventually complete level ℓ and proceed to the critical section: otherwise, it would block at a level higher than ℓ , violating our choice of p_i .

Thus, eventually, p_i would find out that no other process has reached level ℓ and proceed to level $\ell + 1$ or (if $\ell = N - 2$) its critical section —a contradiction.
